Abstract. We propose a symbolic verification method for directory-based consistency protocols working for an arbitrary number of controlled resources and competing processes. We use a graph-based language to specify in a uniform way both client/server interaction schemes and manipulation of directories that contain the access rights of individual clients. Graph transformations model the dynamics of a given protocol. Universally quantified conditions defined on the labels of edges incident to a given node are used to model inspection of directories, invalidation loops and integrity conditions. Our verification procedure computes an approximated backward reachability analysis by using a symbolic representation of sets of configurations. Termination is ensured by using the theory of well-quasi orderings.

1 Introduction

Several implementations of consistency and integrity protocols used in file systems, virtual memory, and shared memory multi-processors are based on client-server architectures. Clients compete to access shared resources (cache and memory lines, memory pages, open files). Each resource is controlled by a server process. In order to get access to a resource, a client needs to start a transaction with the corresponding server. Each server maintains a directory that associates to each client the access rights for the corresponding resource. In real implementations these information are stored into arrays, lists, or bitmaps and are used by the server to take decisions in response to client requests, e.g., to grant access, request invalidation, downgrade access mode or to check integrity of meta-data as in programs like `fschk` used to check Unix-like file-systems. Typically, a server handles a set of resources, e.g. cache lines and directory entries, whose cardinality depends on the underlying hardware/software platform. Consistency protocols however are often designed to work well independently from the number of resources to be controlled, i.e., independently from a given hardware/software configuration.

The need of reasoning about systems with an arbitrary number of resources makes verification of directory-based consistency protocols a quite challenging

task in general. Abstraction techniques operating on the number of resources and/or the number of clients are often applied to reduce the verification task to decidable problems for finite-state (e.g. invisible and environment abstraction in [9, 13]) or Petri net-like models (e.g. counting abstraction used in [16, 14, 24, 25]).

In this paper we propose a new approximated verification technique that operates on models in which both the number of controlled resources and of competing clients is not fixed a priori. Instead of requiring a preliminary abstraction of the model, our method makes use of powerful symbolic representations of parametric system configurations and of dynamic approximation operators applied during symbolic exploration of the state-space.

Our verification method is defined for a specification language in which system configurations are modelled by using a special type of graphs in which vertexes are partitioned into client and server nodes. Client and server nodes are labelled with a set of "states" that represent the current state of the corresponding processes. Labelled edges are used both to define client/server transactions and to describe the local information maintained by each server (e.g. a directory is represented by the set of edges incident to a given server node).

Protocol rules are specified here by rewriting rules that update the state of a node and of one of its incident edges. This very restricted form of graph rewriting naturally models asynchronous communication mechanisms. Furthermore, we admit here guards defined by means of universally quantified conditions on the set of labels of edges of a given node. This kind of guards is important to model operations like inspection of a directory or invalidation cycles without need of abstracting them by means of atomic operations like broadcast in [16, 14]. In order to reason about *parameterized formulations* of consistency protocols we consider here systems in which the size of graphs (number of nodes and edges) is not bounded a priori.

The advantage of working with conditional graph rewriting is twofold. On one side it gives us enough power to formally describe each step of consistency protocols like the full-map coherence protocol [20] in a very detailed way. On the other side it allows us to define (and implement) our verification method at a very abstract level by using graph transformations.

Related Work Parameterized verification methods based finite-state abstractions have been applied to safety properties of consistency protocols and mutual exclusion algorithms. Among these, we mention the *invisible invariants* method [9, 21] and the *environment abstraction* method [13]. Counting abstraction and Petri net-like analysis techniques are considered, e.g., in [16, 14, 24, 25].

Differently from all the previous works, our algorithm is based on graph constraints that allow us to symbolically represent infinite-sets of configurations without need of preliminary finitization of parameters like number of clients, servers, resources, and size of directories. We apply instead dynamic approximation techniques to deal with universally quantified global conditions. We recently used a similar approach for systems with flat configurations (i.e. words) and with a single global context [7]. The new graph-based algorithm is a generalization

of the approach in [7]. Indeed, the symbolic configurations we used in [7] can be viewed as graphs with a single server node and no edges, since global conditions are tested directly on the current process states.

Furthermore, the approximation we propose in this paper is more precise than the monotonic abstraction used to deal with global conditions in our previous work [3–6, 1] (i.e. deletion of processes that do not satisfy the condition). Indeed, consistency property like reachability of a server in state *bad* in the case study presented in Section 4 always return false positives using monotonic abstraction (by deleting all edges that are not in Q we can always move to *bad*). In synthesis the new approach can be viewed as an attempt of introducing more precise approximated verification algorithms for parameterized systems while retaining good features of approaches like counting and monotonic abstraction in [16, 3] like termination properties based on the theory of well-quasi orderings.

Concerning verification algorithms for graph rewriting systems, we are only aware of the works in [18, 22]. We use here different type of graph specifications (e.g. we consider universal quantification on incoming edges) and a different notion of graph-based symbolic representation (i.e. a different entailment relation) with respect to those applied to leader election and routing protocols in [18, 22].

2 A Client/Server Abstract Model

To formalize our abstract model for client/server protocols, we first define a special kind of graphs that we use to represent system configurations. Let Λ_s be a finite set of *server node labels*, Λ_c a finite set of *client node labels*, and Λ_e a finite set of *edge labels*. Furthermore, for $n \in \mathcal{N}$ let $\bar{n} = \{1, \dots, n\}$. A c/s-graph is a tuple $G = (n_c, n_s, E, \lambda_c, \lambda_s, \lambda_e)$, where \bar{n}_s is the set of server nodes, \bar{n}_c is the set of client nodes, $E \subseteq \bar{n}_s \times \bar{n}_c$ is a set of edges connecting a server with a set of clients, and a client with at most one server (i.e. for each $j \in \bar{n}_c$ we require that there exists at most one edge incident in j in E), and $\lambda_c : \bar{n}_c \rightarrow \Lambda_c$, $\lambda_s : \bar{n}_s \rightarrow \Lambda_s$, and $\lambda_e : E \rightarrow \Lambda_e$ are labelling functions.

In the rest of the paper we use the operations on c/s-graphs defined in Fig. 1. A client/server system is a tuple $S = (I, R)$ consisting of a (possibly infinite) set I of c/s-graphs (initial configurations), and a finite set R of rules. We consider here a restricted type of graph rewriting rules to model both the interaction between clients and servers and the manipulation of directories viewed as the set of incident edges in a given server nodes.

The rules have the general form $L \Rightarrow R$ where L is a pattern that has to match (the labels and structure) of a subgraph in the current configuration in order for the rule to be fireable and R describes how the subgraph is rewritten as the effect of the application of the rule. In this paper we are interested in modelling asynchronous communication patterns. Thus, we consider the following patterns: the empty graph \cdot (it matches with any graph); $\langle\langle\ell\rangle\rangle$ that denotes an isolated client node with label ℓ ; $\langle\langle\ell\rangle\rangle$ that denotes a server node with label ℓ , $\langle\langle\ell\rangle\rangle \xleftarrow{\sigma}$ that denotes a client node with label ℓ and incident edge with label σ ; $\langle\langle\ell\rangle\rangle \xleftarrow{\sigma}$ that denotes a server node with label ℓ and an incident edge with label σ .

Given a graph $G = (n_c, n_s, E, \lambda_c, \lambda_s, \lambda_e)$, we define:

- $\text{edges}(G) = E$, $\text{edges}_s(i, G) = \{e \mid e = (i, j) \in E\}$ for $i \in \overline{n_s}$, and $\text{edges}_c(j, G) = \{e \mid e = (i, j) \in E\}$ for $j \in \overline{n_c}$; $\text{label}_e(e, G) = \lambda_e(e)$ for $e \in E$ and $\text{label}_e(i, G) = \{\lambda_e(e) \mid e \in \text{edges}_s(i, G)\}$ for $i \in \overline{n_s}$;
- $\text{add}_e(e, \sigma, G) = (n_c, n_s, E \cup \{e\}, \lambda_c, \lambda_s, \lambda'_e)$ where $\lambda'_e(e) = \sigma$, $\lambda'_e(o) = \lambda_e(o)$ in all other cases;
- $\text{update}_e(e \leftarrow \sigma, G) = (n_c, n_s, E, \lambda_c, \lambda_s, \lambda'_e)$ where $\lambda'_e(e) = \sigma$, and $\lambda'_e(o) = \lambda_e(o)$ in all other cases;
- $\text{del}_e(e, G) = (n_c, n_s, E', \lambda_c, \lambda_s, \lambda'_e)$, where $E' = E \setminus \{e\}$, $\lambda'_e(o) = \lambda_e(o)$ for $o \in E'$.
- $\text{nsiz}_c(G) = n_c$, and $\text{label}_c(i, G) = \lambda_c(i)$ for $i \in \overline{n_c}$;
- $\text{add}_c(P, G) = (n_c + 1, n_s, E, \lambda'_c)$ where $\lambda'_c(n_c + 1) = P$, and $\lambda'_c(o) = \lambda_c(o)$ in all other cases;
- $\text{update}_c(i_1 \leftarrow P_1, \dots, i_m \leftarrow P_m, G) = (n_c, n_s, E, \lambda'_c, \lambda_s, \lambda_e)$ where $\lambda'_c(i_k) = P_k$ for $k : 1, \dots, m$, and $\lambda'_c(o) = \lambda_c(o)$ in all other cases;
- $\text{del}_c(i, G) = (n_c - 1, n_s, E', \lambda'_c, \lambda_s, \lambda'_e)$ where, given the mapping $h_i : \overline{n_c} \rightarrow \overline{n_c - 1}$ defined as $h_i(j) = j$ for $j < i$ and $h_i(j) = j - 1$ for $j > i$, $E' = \{(k, h_i(l)) \mid (k, l) \in E\}$, $\lambda'_c(k) = \lambda_c(p)$ for each $k \in \overline{n_c - 1}$ such that $k = h_i(p)$ and $p \in \overline{n_c}$, $\lambda'_e((k, l)) = \lambda_e((k, q))$ for $(k, l) \in E'$ such that $l = h_i(q)$ for $q \in \overline{n_c}$, $\lambda'_x(o) = \lambda_x(o)$ in all other cases for $x \in \{e, c\}$;
- nsiz_s , label_s , add_s , update_s , and del_s are defined for server nodes in a way similar to the client node operations.

Fig. 1. Definition of basic graph operations.

Furthermore, we also admit a special type of rules in which the rewriting step can be applied to a given server node if a universally quantified condition on the labels of the corresponding incident edges is satisfied. Specifically, we consider the rule schemes illustrated in Fig. 2, where ℓ and ℓ' are node labels of appropriate type, σ and σ' are edge labels, and $\forall Q$ is a condition with $Q \subseteq \Lambda_e$.

With the first two types of rules, we can non-deterministically add a new node to the current graph (e.g. to dynamically inject new servers and clients). With rule *start_transaction*, we non-deterministically select a server and a client (not connected by an already existing edge) add a new edge between them in the current graph (e.g. to dynamically establish a new communication). With rules of types *client/server_steps*, we update the labels of a node with label ℓ and one of its incident edges (non-deterministically chosen) with label σ (e.g. to define asynchronous communication protocols). With rule *test*, we update the node label of a server node i only if all edges incident to i have labels in the set $Q \subseteq \Lambda_e$. With rule *stop_transaction*, we non-deterministically select a client node with label ℓ and incident edge with label σ , and delete such an edge from the current graph (e.g. to terminate a conversation).

It is important to remark that a server has not direct access to the local state of a client. Thus, it cannot check conditions on the global sets of its current clients in an atomic way. For checking global conditions a server can however check the set of its incident edges, i.e., a local snapshot of the current condition

$\cdot \Rightarrow \langle \ell \rangle$	(new_client_node)
$\cdot \Rightarrow \langle \ell \rangle$	(new_server_node)
$\langle \ell \rangle \Rightarrow [\ell'] \xleftarrow{\sigma}$	$(start_transaction)$
$\langle \ell \rangle \xleftarrow{\sigma} \Rightarrow \langle \ell' \rangle \xleftarrow{\sigma'}$	$(server_step)$
$[\ell] \xleftarrow{\sigma} \Rightarrow [\ell'] \xleftarrow{\sigma'}$	$(client_step)$
$\langle \ell \rangle \Rightarrow \langle \ell' \rangle : \forall Q$	$(test)$
$[\ell] \xleftarrow{\sigma} \Rightarrow \langle \ell' \rangle$	$(stop_transaction)$

Fig. 2. Rewriting rules with conditions on edges.

of clients. A consistency protocol should guarantee that the information on the edges (directory) is consistent with the current state of clients.

2.1 Transition Relation

Let G be a c/s-graph. The formula $\forall Q$ is satisfied in server node i if $label_e(i, G) \subseteq Q$. The operational semantics is defined via a binary relation \Rightarrow_r on c/s-graphs such that $G_0 \Rightarrow G_1$ if and only if one of the following conditions hold:

- r is a *new_client_node* rule and $G_1 = add_c(\ell, G_0)$;
- r is a *new_server_node* rule and $G_1 = add_s(\ell, G_0)$;
- r is a *server_step* rule and there exist nodes i and j in G_0 with edge $e = (i, j) \in edges(G)$ such that $label_s(i, G_0) = \ell$, $label_e(e, G_0) = \sigma$, $G_1 = update_e(e \leftarrow \sigma, update_s(i \leftarrow \ell', G_0))$;
- r is a *client_step* rule and there exist nodes i and j in G_0 with edge $e = (i, j) \in edges(G)$ such that $label_n(j, G_0) = \ell$, $label_e(e, G_0) = \sigma$, $G_1 = update_e(e \leftarrow \sigma, update_c(j \leftarrow \ell', G_0))$;
- r is a *start_transaction* rule, there exists in G_0 a client node j with no incident edges in E such that $label_c(j, G_0) = \ell$, and $G_1 = add_e((i, j), \sigma, update_c(j \leftarrow \ell', G_0))$ for a server node i ;
- r is a *stop_transaction* rule, there exist nodes i and j in G_0 such that $label_c(j, G_0) = \ell$, $e = (i, j) \in edges(G_0)$, $label_e(e, G_0) = \sigma$, and $G_1 = del_e(e, update_c(j \leftarrow \ell', G_0))$.

Finally, we define \Rightarrow as $\bigcup_{r \in R} \Rightarrow_r$.

Example 1. As an example, consider a set of labels Λ_n partitioned in the two sets $\Lambda_c = \{idle, wait, use\}$ and $\Lambda_s = \{ready, check, ack\}$, and a set of edge labels $\Lambda_e = \{req, pend, inv, lock\}$. The following set R of rules models a client-server protocol (with any number of clients and servers) in which a server grants the

Fig. 3. Example of execution.

use of a resource after invalidating the client that is currently using it.

$$\begin{aligned}
(r_1) \langle\langle idle \rangle\rangle &\Rightarrow [wait] \xleftrightarrow{req} \\
(r_2) \langle\langle ready \rangle\rangle &\xleftrightarrow{req} \Rightarrow \langle\langle check \rangle\rangle \xleftrightarrow{pend} \\
(r_3) \langle\langle check \rangle\rangle &\xleftrightarrow{lock} \Rightarrow \langle\langle check \rangle\rangle \xleftrightarrow{inv} \\
(r_4) \langle\langle check \rangle\rangle &\Rightarrow \langle\langle ack \rangle\rangle : \forall\{pend, req\} \\
(r_5) \langle\langle ack \rangle\rangle &\xleftrightarrow{pend} \Rightarrow \langle\langle ready \rangle\rangle \xleftrightarrow{lock} \\
(r_6) [use] &\xleftrightarrow{inv} \Rightarrow \langle\langle idle \rangle\rangle \\
(r_7) [wait] &\xleftrightarrow{lock} \Rightarrow [use] \xleftrightarrow{lock}
\end{aligned}$$

With rule r_1 a client non-deterministically creates a new edge connecting to a server. With rule r_2 a server processes a request by changing the edge to *pending*, and then moves to state *check*. With rule r_3 a server sends invalidation messages to the client that is currently using the resource (marked with the special edge *lock*). With rule r_4 a server moves to the acknowledge step whenever all incident edges have state different from *lock* and *inv*. With rule r_5 a server grants the pending request. With rule r_6 a clients releases the resource upon reception of an invalidation request. With rule r_7 a waiting client moves to state *use*.

Now, let us consider an initial graph G_0 with one server node with label *ready* and two client nodes with label *idle*. Then, the following sequence (of graphs) represents an evolution of the graph system (G_0, R) :

$$\begin{aligned}
G_0 = \langle\langle idle \rangle\rangle, \langle\langle idle \rangle\rangle, \langle\langle ready \rangle\rangle &\Rightarrow \langle\langle idle \rangle\rangle, [wait] \xleftrightarrow{req} \langle\langle ready \rangle\rangle \Rightarrow \\
[wait] \xleftrightarrow{req} \langle\langle ready \rangle\rangle &\xleftrightarrow{req} [wait] \Rightarrow [wait] \xleftrightarrow{pend} \langle\langle check \rangle\rangle \xleftrightarrow{req} [wait] \Rightarrow \\
[wait] \xleftrightarrow{pend} \langle\langle ack \rangle\rangle &\xleftrightarrow{req} [wait] \Rightarrow [wait] \xleftrightarrow{lock} \langle\langle ready \rangle\rangle \xleftrightarrow{req} [wait] \Rightarrow \\
[use] \xleftrightarrow{lock} \langle\langle ready \rangle\rangle &\xleftrightarrow{req} [wait] \Rightarrow [use] \xleftrightarrow{lock} \langle\langle check \rangle\rangle \xleftrightarrow{pend} [wait] \Rightarrow \\
[use] \xleftrightarrow{inv} \langle\langle check \rangle\rangle &\xleftrightarrow{pend} [wait] \Rightarrow \langle\langle inv \rangle\rangle, \langle\langle check \rangle\rangle \xleftrightarrow{pend} [wait] \Rightarrow \\
\langle\langle inv \rangle\rangle, \langle\langle ack \rangle\rangle &\xleftrightarrow{pend} [wait] \Rightarrow \langle\langle inv \rangle\rangle, \langle\langle ready \rangle\rangle \xleftrightarrow{lock} [wait] \Rightarrow \\
[inv], [ready] &\xleftrightarrow{lock} [use]
\end{aligned}$$

The first five steps are also drawn in Fig. 3

2.2 Pattern Reachability

In this paper we are interested in studying reachability of graphs containing specific patterns (subgraphs). Patterns can be used to represent bad config-

urations of a graph system. In Example 1 any graph containing the pattern $[use] \xleftarrow{\sigma} (\text{ready}) \xrightarrow{\sigma'} [use]$, for $\sigma, \sigma' \in \Lambda_e$, represents a violation to the exclusive use of a resource controlled by a server node.

To formally define the notion of pattern, we introduce an ordering \preceq on c/s-graphs such that $G \preceq G'$ iff $n_c = \text{nsize}_c(G) \leq m_c = \text{nsize}_c(G')$, $n_s = \text{nsize}_s(G) \leq m_s = \text{nsize}_s(G')$, and there exist injective mappings $h_c : \overline{n}_c \rightarrow \overline{m}_c$ and $h_s : \overline{n}_s \rightarrow \overline{m}_s$ such that

- $\text{label}_c(i, G) = \text{label}_c(h_c(i), G')$ for $i : 1, \dots, n_c$,
- $\text{label}_s(i, G) = \text{label}_s(h_s(i), G')$ for $i : 1, \dots, n_s$,
- for each $e = (i, j) \in \text{edges}(G)$, $e' = (h_c(i), h_s(j)) \in \text{edges}(G')$ and $\text{label}_e(e, G) = \text{label}_e(e', G')$.

A set of c/s-graphs $U \subseteq C$ is *upward closed* with respect to \preceq if $c \in U$ and $c \preceq c'$ implies $c' \in U$. For a c/s-graph G , we use \widehat{G} to denote the upward closure of G , i.e., the set $\{G' \mid G \preceq G'\}$. For sets of c/s-graphs $D, D' \subseteq C$ we use $D \Rightarrow D'$ to denote that there are $G \in D$ and $G' \in D'$ with $G \Rightarrow G'$.

The *Pattern Reachability Problem* for graph systems is defined as follows:

PATTERN REACHABILITY PROBLEM (PRP)

Instance

- A graph system $\mathcal{P} = (I, R)$.
- A finite set C_F of c/s-graphs

Question $G_0 \Rightarrow^* \widehat{C}_F$ for $G_0 \in I$?

Typically, \widehat{C}_F (which is an infinite set) is used to characterize sets of *bad* configurations which we do not want to occur during the execution of the system. In such a case, the system is safe iff \widehat{C}_F is not reachable. Therefore, checking safety properties amounts to solving PRP (i.e., to the reachability of upward closed sets).

The following results then hold.

Proposition 1. *PRP is undecidable.*

Proof. Control state reachability for counter machines can be reduced to PRP. We use server node s_i to control the i -th counter. We use client processes with label aux_1 connected to a server with edges labelled 1 to represent the current value of the corresponding counter. We use a special client process c to keep track of the current control location and to fire the operations on counters. For instance, to simulate the instruction $L : \text{inc}(c_i); \text{goto } L'$, we proceed as follows. In state L client process c starts a transaction with server s_i . During the transaction, s_i , activated by c , accepts a new connection with an aux process, i.e., s_i changes the corresponding edge label to 1. We assume here that we can produce an arbitrary number of aux processes, and that they are always ready to connect to any server (they are created with state aux_0 and change state into aux_1 when connected to a server with an edge labelled 0). After the connection

$$\begin{array}{ll}
\text{Instruction : } \ell_1 : \text{inc}(c_i); \text{goto } \ell_2 & \text{Instruction : } \ell_1 : \text{dec}(c_i); \text{goto } \ell_2 \\
(i_1) \langle \ell_1 \rangle \Rightarrow [\text{wait}_{\ell_2}] \xrightarrow{\text{req_inc}_i} & (d_1) \langle \ell_1 \rangle \Rightarrow [\text{wait}_{\ell_2}] \xrightarrow{\text{req_dec}_i} \\
(i_2) (c_i) \xrightarrow{\text{req_inc}_i} \Rightarrow (inc_i) \xrightarrow{\text{pend}} & (d_2) (c_i) \xrightarrow{\text{req_dec}_i} \Rightarrow (dec_i) \xrightarrow{\text{pend}} \\
(i_3) (inc_i) \xrightarrow{0} \Rightarrow (grant_i) \xrightarrow{1} & (d_3) (dec_i) \xrightarrow{1} \Rightarrow (grant_i) \xrightarrow{0} \\
(i_4) (grant_i) \xrightarrow{\text{pend}} \Rightarrow (c_i) \xrightarrow{\text{ack}} & (d_4) (grant_i) \xrightarrow{\text{pend}} \Rightarrow (c_i) \xrightarrow{\text{ack}} \\
(i_5) [\text{wait}_{\ell_2}] \xrightarrow{\text{ack}} \Rightarrow \langle \ell_2 \rangle & (d_5) [\text{wait}_{\ell_2}] \xrightarrow{\text{ack}} \Rightarrow \langle \ell_2 \rangle
\end{array}$$

$$\begin{array}{ll}
\text{Instruction : } \ell_1 : \text{test}(c_i); \text{goto } \ell_2 & \text{Rules for "aux" processes} \\
(t_1) \langle \ell_1 \rangle \Rightarrow [\text{wait}_{\ell_2}] \xrightarrow{\text{req_test}_i} & (a_1) \cdot \Rightarrow \langle aux_0 \rangle \\
(t_2) (c_i) \xrightarrow{\text{req_test}_i} \Rightarrow (test_i) \xrightarrow{\text{pend}} & (a_2) \langle aux_0 \rangle \Rightarrow [aux_1] \xrightarrow{0} \\
(t_3) (test_i) \Rightarrow (grant_i) : \forall \{pend, 0\} & \\
(t_4) (grant_i) \xrightarrow{\text{pend}} \Rightarrow (c_i) \xrightarrow{\text{ack}} & \\
(t_5) [\text{wait}_{\ell_2}] \xrightarrow{\text{ack}} \Rightarrow \langle \ell_2 \rangle &
\end{array}$$

Fig. 4. Encoding of Counter Machines.

Fig. 5. Encoding of a configuration of a two counter machine with location L and counters $c_1 = 2$, and $c_2 = 1$.

is established, s_i sends an acknowledge back to c . c now stops the transaction and updates its label to L' . Notice that client c migrates from one server to another during the simulation of instructions.

Decrement and zero- test are simulated in a similar way. In particular, decrement can be simulated by requesting s_i to disable the connection with an aux process (e.g. for brevity to update the edge label from 1 to 0 or with some more transition to disconnect from s_i), and for the zero-test s_i checks that all of its incident edges have state different from 1. For this purpose, s_i can use a $test$ rule.

A counter c_i with value k is represented by the graph in which the server for c_i is connected via edges labelled by 1 to k auxiliary processes (other auxiliary processes can be connected to the same server but the corresponding edges must be labelled 0). We give an example in Fig. 5. The rules used in the encoding are shown in Fig. 4.

Fig. 6. A graph constraint G (a), and a c/s-graph in $\llbracket G \rrbracket$ (b).

3 Approximated Verification Algorithm

In this section we propose an approximated verification algorithm based on the notion of *graph constraints*, a special symbolic representation of an infinite set of c/s-graphs.

3.1 Graph Constraints

We use the following symbolic representation of infinite set of c/s-graphs.

A *graph constraint* (gc) is a graph $\Psi = (n_c, n_s, E, \rho_c, \rho_s, \rho_e)$, with client nodes $\{1, \dots, n_c\}$, server nodes $\{1, \dots, n_s\}$, edges in $E \subseteq \overline{n_s} \times \overline{n_c}$, and labels defined by maps $\rho_c : \overline{n_c} \rightarrow \Lambda_c$, $\rho_s : \overline{n_s} \rightarrow (\Lambda_s \times 2_e^\Lambda)$, and $\rho_e : E \rightarrow \Lambda_e$.

Notice that, in a graph constraint Ψ , the label of a server node is a pair (ℓ, Q) where ℓ is a node label and $Q \subseteq \Lambda_e$ is a subset of edge labels, called *padding set*.

Notation: In this section we adapt the operations on c/s-graphs to graph constraints. Specifically, given $\Psi = (n_c, n_s, E, \rho_c, \rho_s, \rho_e)$, $i \in \overline{n_s}$, $j \in \overline{n_c}$, $\rho_s(i) = (\ell, Q)$, $\rho_c(j) = \ell'$, and $e \in E$, then $\text{label}_s(i, \Psi) = \ell$, $\text{label}_p(i, \Psi) = Q$, $\text{label}_c(j, \Psi) = \ell'$, and $\text{label}_e(e, \Psi) = \rho_e(e)$. The other operations are defined as for c/s-graphs.

For a graph constraint Ψ to be well-formed (wfgc), we require that $\text{label}_e(i, \Psi) \subseteq \text{label}_p(i, \Psi)$ for each $i \in \overline{n_s}$.

Let Ψ be a wfgc, and G be a c/s-graph. We define a relation \preceq such that $\Psi \preceq G$ iff $n_c = \text{nsiz}_c(\Psi) \leq m_c = \text{nsiz}_c(G)$, $n_s = \text{nsiz}_s(\Psi) \leq m_s = \text{nsiz}_s(G)$, and there exists injective mappings $h_c : \overline{n_c} \rightarrow \overline{m_c}$ and $h_s : \overline{n_s} \rightarrow \overline{m_s}$ such that

- $\text{label}_c(i, \Psi) = \text{label}_c(h_c(i), G)$ for $i : 1, \dots, n_c$,
- $\text{label}_s(i, \Psi) = \text{label}_s(h_s(i), G)$ and $\text{label}_e(h_s(i), G') \subseteq \text{label}_p(i, \Psi) = Q$ for $i : 1, \dots, n_s$;
- for each $e = (i, j) \in \text{edges}(\Psi)$, $e' = (h_s(i), h_c(j)) \in \text{edges}(G)$ and $\text{label}_e(e, \Psi) = \text{label}_e(e', G)$.

The denotation of a graph constraint Ψ is defined as $\llbracket \Psi \rrbracket = \{G \mid G \text{ is a c/s-graph, } \Psi \preceq G\}$. In Fig. 6 we give an example of wfgc (a), and of one of its instances (b).

3.2 Operations on Graph Constraints

Approximated Predecessor Relation The set of predecessors of a set S of c/s-graphs computed with respect to a rule r is defined as

$$pre_r(S) = \{G \mid G \Rightarrow_r S\}$$

Given a wfgc Ψ we now define a relation \sim_r working on wfgc's that we use to overapproximate the set $\llbracket \Psi \rrbracket \cup pre_r(\llbracket \Psi \rrbracket)$. We consider here the union of these two sets in order to be able to discard graph constraints that denote graphs already contained in $\llbracket \Psi \rrbracket$.

Specifically, for graph constraints Ψ , with $n_s = \text{nsizes}(\Psi)$ and $n_c = \text{ncsizes}(\Psi)$, and Ψ' , and a rule $r \in R$, the relation $\Psi \sim_r \Psi'$ is defined as follows:

server-step: r is the rule $(\ell) \xleftarrow{\sigma} \Rightarrow (\ell') \xleftarrow{\sigma'}$ and one of the following conditions hold

- $i \in \overline{n_s}, j \in \overline{n_c}, e = (i, j) \in \text{edges}(\Psi), \text{label}_s(i, \Psi) = \ell', \text{label}_e(e) = \sigma',$ and

$$\Psi' = \text{update}_e(e, \sigma, \text{update}_s(i \leftarrow (\ell, Q), \Psi))$$

where $Q = \text{label}_p(i) \cup \{\sigma\}$.

In this case we update the label of an existing edge (i, j) and of the node i with the labels σ and ℓ , respectively. They represent the preconditions for firing the rule. Furthermore, we augment the padding set of i with label σ . Notice that here we apply an approximation, i.e., as soon as we add σ we allow any number of occurrences of edges with label σ but we do not count them. The label of client node j is not modified.

- $i \in \overline{n_s}, j \in \overline{n_c}, \text{edges}(j, \Psi) = \emptyset$ (j has no incident edges), $\text{label}_s(i, \Psi) = \ell', \sigma' \in \text{label}_p(i, \Psi),$ and

$$\Psi' = \text{add}_e((i, j), \sigma, \text{update}_s(i \leftarrow (\ell, Q), \Psi))$$

where $Q = \text{label}_p(i, \Psi) \cup \{\sigma\}$.

Although not explicitly present, we assume here that the edge (i, j) with label σ' is in the upward closure of Ψ (this can happen only if j is not involved in other explicit edges). We add the edge (i, j) with label σ since its presence is a precondition for the firing the rule. Furthermore, we update the label of i as in the first case.

- $i \in \overline{n_s}, \text{label}_s(i, \Psi) = \ell', \sigma' \in \text{label}_p(i, \Psi),$ and

$$\Psi' = \text{add}_e((i, n_c + 1), \sigma, \text{add}_c(\ell'', \text{update}_s(i \leftarrow (\ell, Q), \Psi)))$$

where $Q = \text{label}_p(i, \Psi) \cup \{\sigma\}$, and ℓ'' is non-deterministically chosen from Λ_c . Although not explicitly present, we assume here that both the client node $n_c + 1$ (with some label taken from Λ_c) and the edge $(i, n_c + 1)$ with label σ are in the upward closure of Ψ . We add them to Ψ since their presence is a precondition for the firing of r . We update the label of i as in the other

two cases. Notice that the dimension of the graph constraint is increased by one, since we insert the new node $n_c + 1$.

For this kind of rules, there are two remaining cases to consider (the edge and the server node, or the edge and both server and client nodes are not explicitly present in Ψ). However these cases give rise to graph constraints that are redundant with respect to Ψ . Thus, we can discard them without loss of precision (we recall that our aim is to symbolically represent $\llbracket \Psi \rrbracket \cup pre_r(\llbracket \Psi \rrbracket)$).

client-step: r is the rule $[\ell] \xleftarrow{\sigma} \Rightarrow [\ell'] \xleftarrow{\sigma'}$ and one of the following conditions hold

- $i \in \overline{n_s}, j \in \overline{n_c}, e = (i, j) \in \text{edges}(\Psi), \text{label}_c(j, \Psi) = \ell', \text{label}_e(e) = \sigma',$ and

$$\Psi' = \text{update}_e(e, \sigma, \text{update}_s(i \leftarrow (\text{label}_s(i, \Psi), Q), \text{update}_c(j \leftarrow \ell, \Psi)))$$

where $Q = p(i, \Psi) \cup \{\sigma\}$.

In this case we update the label of an existing edge (i, j) and of the node j with the labels σ and ℓ as a precondition for the firing of the rule r . Furthermore, we add σ to the set of admitted edge labels of server node i .

- $i \in \overline{n_s}, j \in \overline{n_c}, \text{edges}(j, \Psi) = \emptyset$ (j has no incident edges), $\text{label}_c(j, \Psi) = \ell', \sigma' \in \text{label}_p(i, \Psi),$ and

$$\Psi' = \text{add}_e((i, j), \sigma, \text{update}_s(i \leftarrow (\text{label}_s(i, \Psi), Q), \text{update}_c(j \leftarrow \ell, \Psi)))$$

where $Q = \text{label}_p(i, \Psi) \cup \{\sigma\}$.

Although not explicitly present, we assume here that the edge (i, j) is in the upward closure of Ψ . We add the edge (i, j) with label σ since its presence is a precondition for the firing of the rule. Furthermore, we update the label of i and j as in the first case.

- $j \in \overline{n_c}, \text{edges}(j, \Psi) = \emptyset$ (j has no incident edges), $\text{label}_c(j, \Psi) = \ell',$ and

$$\Psi' = \text{add}_e((n_s + 1, j), \sigma, \text{add}_s((\ell'', \Lambda_e), \text{update}_c(j \leftarrow \ell, \Psi)))$$

where $\ell'' \in \Lambda_s$. Although not explicitly present, we assume here that the edge $(n_s + 1, j)$, for a new server node $n_s + 1$ with a label in Λ_s , is in the upward closure of Ψ . We add the node and the edge with label σ since its presence is a precondition for firing the rule. Furthermore, we update the label of j as in the first case.

- $i \in \overline{n_s}, \sigma' \in \text{label}_p(i, \Psi),$ and

$$\Psi' = \text{add}_e((i, n_c + 1), \sigma, \text{add}_c(\ell, \text{update}_s(i \leftarrow (\text{label}_s(i, \Psi), Q), \Psi)))$$

where $Q = \text{label}_p(i, \Psi) \cup \{\sigma\}$.

Although not explicitly present, we assume here that both the node $n_c + 1$ and the edge $(i, n_c + 1)$ are in the upward closure of Ψ . We add it with label σ to the set of edges and update the label of i including σ in the set of admitted edges. Notice that there are remaining cases (client, server,

and edge are not explicitly present in Ψ). However these cases give rise to a graph constraint that is redundant with respect to Ψ . Thus, we can discard it without loss of precision (we recall that our aim is to symbolically represent $\llbracket \Psi \rrbracket \cup pre_r(\llbracket \Psi \rrbracket)$).

start-transaction: r is the rule $\langle\langle \ell \rangle\rangle \Rightarrow \llbracket \ell' \rrbracket \xleftarrow{\sigma}$ and one of the following conditions hold

- $i \in \overline{n_s}, j \in \overline{n_c}, e = (i, j) \in \text{edges}(i, E), \text{label}_c(j, \Psi) = \ell', \text{label}_e(e, \Psi) = \sigma$, and

$$\Psi' = \text{update}_c(j \leftarrow \ell, \text{del}_e(\Psi, e))$$

Since we reason backwards, in this case we delete an existing edge (i, j) with label σ and update the label of node j .

- $i \in \overline{n_s}, j \in \overline{n_c}, \text{label}_c(j, \Psi) = \ell', \text{edges}(j, E) = \emptyset, \sigma \in \text{label}_p(i, \Psi)$, and

$$\Psi' = \text{update}_c(j \leftarrow \ell, \Psi)$$

Here we assume that the edge between two existing nodes, namely the client node j with label ℓ' , and the server node i , is not explicitly represented in Ψ . In this case we simply update the label of client node j .

- $j \in \overline{n_c}, \text{label}_c(j, \Psi) = \ell'$

$$\Psi' = \text{add}_s((\ell'', \Lambda_e), \text{update}_c(j \leftarrow \ell, \Psi))$$

where ℓ'' is non-deterministically chosen from Λ_s .

Here we assume that both the edge and the node connected to j with label ℓ' are not explicitly represented. In this case we update the label of node j and require the presence of a new server node with a label non-deterministically chosen from Λ_s . The set of admitted labels of the new node is the largest possible one (Λ_e).

Test: r is the rule $\langle\langle \ell \rangle\rangle \Rightarrow \langle\langle \ell' \rangle\rangle : \forall Q$ and one of the following conditions hold

- $i \in \overline{n_s}, \text{label}_s(i, \Psi) = \ell', R = \text{label}_p(i, \Psi) \cap Q, \text{label}_e(e) \in R$ for each $e \in \text{edges}(i, \Psi)$, and

$$\Psi' = \text{update}_s(i \leftarrow (\ell, R), \Psi)$$

In this rule the padding $\text{label}_p(i, \Psi)$ associated to a node i with label ℓ' plays a crucial role. We first check that the current set of labels of edges incident to i is contained into the intersection R of $\text{label}_p(i, \Psi)$ and Q . If this condition is satisfied, we restrict the padding of node i to be the set R (precondition for firing the rule) and update the label of i to ℓ . This rule cannot be applied whenever there are edges in $\text{edges}(i, \Psi)$ with labels not in R . If R is the empty set, then the node i must be isolated.

Given a wfgc Ψ , we define $\Psi \rightsquigarrow$ as the set $\{\Psi' \mid \Psi \longrightarrow \Psi'\}$. The following property then holds.

Lemma 1. $(\llbracket \Psi \rrbracket \cup pre(\llbracket \Psi \rrbracket)) \subseteq (\llbracket \Psi \rrbracket \cup \llbracket \Psi \rightsquigarrow \rrbracket)$.

Entailment Test We now define an entailment relation \sqsubseteq used to compare denotations of graph constraints. Let Ψ and Ψ' be two wfgc such that $\text{nsiz}_c(\Psi) = n_c$, $\text{nsiz}_s(\Psi) = n_s$, $\text{nsiz}_c(\Psi') = m_c$, and $\text{nsiz}_s(\Psi') = m_s$. The relation $\Psi \sqsubseteq \Psi'$ holds iff $n_c \leq m_c$, $n_s \leq m_s$, and there exists injective mappings $h_c : \overline{n_c} \rightarrow \overline{m_c}$ $h_s : \overline{n_s} \rightarrow \overline{m_s}$ such that

- $\text{label}_s(i, \Psi) = \text{label}_s(h_s(i), \Psi')$ for $i \in \overline{n_s}$,
- $\text{label}_c(j, \Psi) = \text{label}_c(h_c(j), \Psi')$ for $j \in \overline{n_c}$,
- $\text{label}_p(h_s(i), \Psi') \subseteq \text{label}_p(i, \Psi)$ for $i \in \overline{n_s}$,
- for each $e = (i, j) \in E$, $e' = (h_s(i), h_c(j)) \in E'$ and $\text{label}_e(e, \Psi) = \text{label}_{e'}(e', \Psi')$.

The following property then holds.

Lemma 2. *Given Ψ and Ψ' , $\Psi \sqsubseteq \Psi'$ implies $\llbracket \Psi' \rrbracket \subseteq \llbracket \Psi \rrbracket$.*

We naturally extend the entailment relation to finite sets of constraints as follows. Given two sets of graph constraints Φ, Φ' , $\Phi \sqsubseteq \Phi'$ iff for each $\Psi' \in \Phi'$ there exists $\Psi \in \Phi$ such that $\Psi \sqsubseteq \Psi'$.

3.3 Backward Reachability

We use the relation \rightsquigarrow to define a symbolic backward reachability algorithm for approximating solutions to PRP. We start with a finite set Φ_F of graph constraints denoting an infinite set of bad graph configurations. We generate a sequence $\Phi_0, \Phi_1, \Phi_2, \dots$ of finite sets of constraints such that $\Phi_0 = \Phi_F$, and $\Phi_{j+1} = \Phi_j \cup (\Phi_j \rightsquigarrow)$. Since $\llbracket \Phi_0 \rrbracket \subseteq \llbracket \Phi_1 \rrbracket \subseteq \llbracket \Phi_2 \rrbracket \subseteq \dots$, the procedure terminates when we reach a point j where $\Phi_j \sqsubseteq \Phi_{j+1}$. Notice that the termination condition implies that $\llbracket \Phi_j \rrbracket = (\bigcup_{0 \leq i \leq j} \llbracket \Phi_i \rrbracket)$. By Lemmas 1, Φ_j denotes an over-approximation of the set of all predecessors of $\llbracket \Phi_F \rrbracket$. This means that if $(I \cap \llbracket \Phi_j \rrbracket) = \emptyset$, then there exists no $G \in \llbracket \Phi_F \rrbracket$ with $G_0 \Rightarrow^* G$ for $G_0 \in I$. Thus, the procedure can be used as a semi-test for checking PRP.

3.4 Termination

The termination of our verification procedure is ensured by the property that the entailment relation of graph constraints is a well-quasi ordering. This property follows from the fact that a c/s-graph with n_s server nodes and n_c client nodes can be given an alternative representation as a bag of tuples of a special form. To obtain this representation, we first need to transform a c/s-graph G in a finite set of *completed graphs* in which every client node is connected to a server node.

Assume that G has k isolated client nodes. The set S_G of completed graphs is built by considering all wfgcs's obtained by (a) adding $k' \leq k$ new server nodes such that each new node has a label (ℓ, Λ_e) with ℓ non-deterministically chosen from Λ_s , (b) connecting isolated client nodes to a non-deterministically chosen server node with a label (ℓ', Q) by means of an edge with a label non-deterministically chosen from Q .

Fig. 7. A graph constraint G (a), and two of its possible completions (b-c).

Given a c/s-graph G , we call S_G the set of all possible completed graphs associated to G . We give an example in Fig. 7. A completed graph can now be represented as a *bag* (multiset) of tuples of the form (s_i, Q_i, M_i) for $i \in \{1, \dots, n_s\}$ where

- $s_i \in A_s$ is the label of the server node i ,
- $Q_i \in 2^{A_e}$ is the padding associated to i ,
- if i has client nodes j_1, \dots, j_{k_i} connected to it M_i is a bag $\{p_1, \dots, p_{k_i}\}$ such that $p_l = (\sigma_l, c_l)$, where σ_l is the label of the edge incident to node j_l and c_l is the label of node j_l .

Given two of such bags m_1 and m_2 , we define $m_1 \leq m_2$ if each tuple (s, Q, M) in m_1 can be injected in a tuple (s', Q', M') in m_2 such that $s = s'$, $Q' \subseteq Q$ and M is contained into M' (multiset containment).

Entailment of two graph constraints G and G' can now be reformulated over the corresponding sets of completed graphs, i.e., $G \sqsubseteq G'$ iff for each $H' \in S_{G'}$ there exists $H \in S_G$ such that $H \leq H'$.

4 A Case Study

We consider here the *full-map cache coherence protocol* described in [20]. This protocol is defined for a multiprocessor with shared memory and local caches in which the memory controller maintains a directory for each memory line with information about its use, i.e., the line is shared between different caches or used in exclusive mode by a given cache. The directory is used to optimize the invalidation and downgrade phase required when a processor sends a new request for exclusive or shared use. The protocol is informally defined by the following steps; we use M to denote the controller of a memory line, and C to denote the controller of a cache line.

req_ex: C sends a **req_ex** message to M for requesting exclusive use of a memory line and then moves to a waiting state.

rec_inv: Upon reception of **req_ex** and when not processing other requests M locks the line, stores the identifier of the requesting cache controller, and starts an invalidation phase. In this phase M sends a message **req_inv** to all caches in the directory marked as *shared* or *exclusive*.

ack_inv: Upon receipt of message **req_inv** coming from M , cache C invalidates its line and sends an acknowledgment **ack_inv** to M .

grant_ex: Memory controller terminates the invalidation phase after having received acknowledgments from all cache controllers in the directory. Memory controller sends a message **grant_ex** to the cache controller who sent the **req_ex** message and adds its identifier in the directory (marked as *exclusive*). A waiting cache receives the message **grant_ex** and moves to state **exclusive**.

req_sh: C sends a **req_sh** message to M for requesting shared use of a memory line and then moves to a waiting state.

rec_dg: Upon reception of **req_sh** and when not processing other requests M locks the line, stores the identifier of the requesting cache controller, and starts a downgrade phase. In this phase M sends a message **req_sh** to all caches in the directory marked as *shared* or *exclusive*.

ack_dg: Upon receipt of message **req_sh** coming from M , cache C (in state *shared* or *exclusive*) downgrade its state to *shared* and sends an acknowledgment **ack_sh** to M .

grant_sh: Memory controller terminates the downgrade phase after having received acknowledgments from all cache controllers in the directory. Memory controller sends a message **grant_sh** to the cache controller who sent the **req_sh** message and adds its identifier to the directory (marked as *shared*). A waiting cache receives the message **grant_sh** and moves to state **shared**.

replacement: As a result of a replacement strategy, the cache controller invalidates a cache line in state **exclusive/shared**.

We model this protocol by means of a client/server system with a set of labels Λ_n partitioned in the two sets

$$\begin{aligned} \Lambda_c &= \{inv, wait, shared, exclusive\} && (cache\ nodes) \\ \Lambda_s &= \{idle, inv_loop, dg_loop, ack_ex, ack_sh\} && (memory\ nodes) \end{aligned}$$

and a set of edge labels

$$\Lambda_e = \{req_ex, req_sh, req_inv, req_dg, pending, sh, ex\}$$

We recall that in our model we assume to have an arbitrary number of memory line each one controlled by a distinct memory node with labels in Λ_s and an arbitrary number of cache lines each one controlled by one controller with labels in Λ_c .

The initial graph configurations consist then of any number of isolated nodes with label *inv* or *idle*. Furthermore, we can use the rules

$$\cdot \Rightarrow \langle\langle inv \rangle\rangle \quad \cdot \Rightarrow \langle\langle idle \rangle\rangle$$

to add dynamic creation of new cache and memory line controllers. During its life cycle the same cache line can be associated to different memory lines. However, at any given instant a cache line is either invalid or contains a copy of a given memory block. A memory line however can be copied into several cache lines.

$$\begin{aligned}
(c_1) \langle\langle inv \rangle\rangle &\Rightarrow [wait] \xleftrightarrow{req-ex} \\
(c_2) \langle\langle inv \rangle\rangle &\Rightarrow [wait] \xleftrightarrow{req-sh} \\
(c_3) [shared] &\xleftrightarrow{req-inv} \Rightarrow \langle\langle inv \rangle\rangle \\
(c_4) [exclusive] &\xleftrightarrow{req-inv} \Rightarrow \langle\langle inv \rangle\rangle \\
(c_5) [exclusive] &\xleftrightarrow{req-dg} \Rightarrow [shared] \xleftrightarrow{sh} \\
(c_6) [wait] &\xleftrightarrow{ex} \Rightarrow [exclusive] \xleftrightarrow{ex} \\
(c_7) [wait] &\xleftrightarrow{sh} \Rightarrow [shared] \xleftrightarrow{sh} \\
(c_8) [shared] &\xleftrightarrow{sh} \Rightarrow \langle\langle inv \rangle\rangle \\
(c_9) [exclusive] &\xleftrightarrow{ex} \Rightarrow \langle\langle inv \rangle\rangle
\end{aligned}$$

Fig. 8. Rules for cache controllers.

The graph rules that model the interaction between the controller of a cache line and that of a memory line are shown in Fig. 8. With rule c_1 and c_2 , a cache controller sends resp. a req_ex and a req_sh message to a memory controller chosen non-deterministically, and then moves to a waiting state. A request is modelled here as creation of a new edge. As mentioned before, we assume that a cache node has at most one edge. The non-determinism in the choice of the server node models the fact that the association between a cache line and a memory line depends on the memory address contained in the operations issued on the local processor. Rule c_3 and c_4 model the reception of an invalidation request, and consequent invalidation of the cache node, coming from a server node. Rule c_5 models the reception of a downgrade request coming from a server node and the consequent passage from state $exclusive$ to state $shared$. The label of the edge is changed to sh . Rule c_6 and c_7 model reception (in state $wait$) of the grant for exclusive (edge with label ex) or shared use (edge with label sh) for the requested memory line. Rule c_8 and c_9 model the invalidation of the cache line requested by the local processor (e.g. for replacing the current cache line with another memory line). After applying one of these rules, a cache node disconnected from memory node m can be connected to another memory node m' using rules c_1 and c_2 , and so on. The graph rules that model the interaction between the controller of a memory line and the cache controllers are shown in Fig. 9. Rules $m_1 - m_5$ model the steps needed to grant a req_ex request for a memory line M . In rule m_1 a memory node locks the memory line M by moving to state inv_loop (starting point of invalidation phase) and remembers the identity of the corresponding requesting node by marking the edge with label $pending$. Rule $m_2 - m_4$ model the invalidation phase. We use again edges to simulate the inspection of the full-map. For each edge with label ex/sh we send a req_inv message to the corresponding node. Notice that we do not inspect the current state of the nodes. Invalidation is only based on edge labels. Rule m_4 corresponds to the termination of the invalidation step. We require here that all ex and req_inv messages have adequately been processed during the invalidation phase. In rule m_5 we grant exclusive use to the requesting cache controller.

$$\begin{aligned}
(m_1) \text{ (idle)} &\xleftrightarrow{req_ex} \Rightarrow \text{ (inv_loop)} \xleftrightarrow{pend} \\
(m_2) \text{ (inv_loop)} &\xleftrightarrow{ex} \Rightarrow \text{ (inv_loop)} \xleftrightarrow{req_inv} \\
(m_3) \text{ (inv_loop)} &\xleftrightarrow{sh} \Rightarrow \text{ (inv_loop)} \xleftrightarrow{req_inv} \\
(m_4) \text{ (inv_loop)} &\Rightarrow \text{ (ack_inv)} : \forall \{pend, req_sh, req_ex\} \\
(m_5) \text{ (ack_inv)} &\xleftrightarrow{pend} \Rightarrow \text{ (idle)} \xleftrightarrow{ex} \\
(m_6) \text{ (idle)} &\xleftrightarrow{req_sh} \Rightarrow \text{ (inv_dg)} \xleftrightarrow{pend} \\
(m_7) \text{ (inv_dg)} &\xleftrightarrow{ex} \Rightarrow \text{ (inv_dg)} \xleftrightarrow{req_dg} \\
(m_8) \text{ (inv_dg)} &\Rightarrow \text{ (ack_dg)} : \forall \{sh, pend, req_sh, req_ex\} \\
(m_9) \text{ (ack_dg)} &\xleftrightarrow{pend} \Rightarrow \text{ (idle)} \xleftrightarrow{sh}
\end{aligned}$$

Fig. 9. Rules for memory controllers.

Similarly, rules $m_6 - m_{10}$ model the steps needed to grant a req_sh request. The difference here is that instead of an invalidation request we only send a downgrade request to a cache node marked as exclusive (with edge ex). Rule m_8 terminates this phase by checking that there are no pending req_inv requests and that the full-map has been completely inspected. Finally, rule m_9 is used to grant shared access to the requesting cache (that connected with the server node with a *pending* edge).

4.1 Optimized full-map cache coherence protocol.

We now consider an optimized version of the *full-map coherence protocol* in which memory controllers associate a special flag $mode_ex$ to each line to remember when the line is in exclusive use (i.e. without need to inspect the full-map). We describe below how the protocol changes.

req_ex The optimization in the processing of message req_ex is the following.

When $mode_ex = 1$ M sends a message **req_inv** only to the cache marked as *exclusive*.

req_sh The optimization in the processing of message req_sh is the following.

When $mode_ex = 1$ M sends a message **req_dg** only to the cache marked as *exclusive*.

replacement In the optimized version we need a more detailed description of this phase. The cache controller sends a replacement message to the memory controller. The memory controller resets the corresponding bit in the full-map and sends back an invalidation request to the cache controller. If $mode_ex = 1$ then the flag is set to 0.

We model the optimized protocol in the following way. First, we add the label req_rep to Λ_e and the new labels $idle_ex, ex_inv_1, ex_inv_2, ex_inv_3, ex_inv_4$ for server nodes. A cache controller is modelled via rules c_1, \dots, c_7 of Fig. 8 plus the two new rules of Fig. 10 that describe a replacement message sent to the memory controller: A memory controller is modelled via rules $(m_1) - (m_4), (m_6) - (m_{10})$ in

$$\begin{aligned}
(c_8) \text{ [shared]} &\xleftrightarrow{sh} \Rightarrow \text{ [shared]} \xleftrightarrow{req_rep} \\
(c_9) \text{ [exclusive]} &\xleftrightarrow{ex} \Rightarrow \text{ [exclusive]} \xleftrightarrow{req_rep}
\end{aligned}$$

Fig. 10. Additional rules for cache controller.

$$\begin{aligned}
(m_5) \text{ (ack_inv)} &\xleftrightarrow{pend} \Rightarrow \text{ (idle_ex)} \xleftrightarrow{ex} \\
(m_{11}) \text{ (inv_loop)} &\xleftrightarrow{req_rep} \Rightarrow \text{ (inv_loop)} \xleftrightarrow{req_inv} \\
(m_{12}) \text{ (inv_dg)} &\xleftrightarrow{req_rep} \Rightarrow \text{ (inv_dg)} \xleftrightarrow{req_inv} \\
(m_{13}) \text{ (idle_ex)} &\xleftrightarrow{req_ex} \Rightarrow \text{ (ex_inv}_1\text{)} \xleftrightarrow{pend} \\
(m_{14}) \text{ (ex_inv}_1\text{)} &\xleftrightarrow{ex} \Rightarrow \text{ (ex_inv}_2\text{)} \xleftrightarrow{req_inv} \\
(m_{15}) \text{ (ex_inv}_1\text{)} &\xleftrightarrow{req_rep} \Rightarrow \text{ (ex_inv}_2\text{)} \xleftrightarrow{req_inv} \\
(m_{16}) \text{ (idle_ex)} &\xleftrightarrow{req_sh} \Rightarrow \text{ (ex_inv}_3\text{)} \xleftrightarrow{pend} \\
(m_{17}) \text{ (ex_inv}_3\text{)} &\xleftrightarrow{ex} \Rightarrow \text{ (ex_inv}_4\text{)} \xleftrightarrow{req_dg} \\
(m_{18}) \text{ (ex_inv}_3\text{)} &\xleftrightarrow{req_rep} \Rightarrow \text{ (ex_inv}_4\text{)} \xleftrightarrow{req_inv} \\
(m_{19}) \text{ (ex_inv}_2\text{)} &\Rightarrow \text{ (ack_inv)} : \forall \{pend, req_sh, req_ex\} \\
(m_{20}) \text{ (ex_inv}_4\text{)} &\Rightarrow \text{ (ack_dg)} : \forall \{pend, req_sh, req_ex, sh\} \\
(m_{21}) \text{ (idle)} &\xleftrightarrow{req_rep} \Rightarrow \text{ (idle)} \xleftrightarrow{req_inv} \\
(m_{22}) \text{ (idle_ex)} &\xleftrightarrow{req_rep} \Rightarrow \text{ (idle)} \xleftrightarrow{req_inv}
\end{aligned}$$

Fig. 11. Additional rules for a memory controller.

addition to the following new rules: The new rule m_5 is used to set the $mode_ex$ flag to 1 (represented by state $idle_ex$). Rules $m_{11} - m_{12}$ are used to handle pending req_rep during an invalidation loop with $mode_ex = 0$. Rules $m_{13} - m_{15}$ (for req_ex) and $m_{16} - m_{20}$ (for req_sh) model the fast invalidation phases required when $mode_ex = 1$ (we just have to invalidate one cache controller). Rules $m_{21} - m_{22}$ model the acknowledgment to req_rep messages resp. when $mode_ex = 0$ and $mode_ex = 1$. In the latter case the flag is set to zero (i.e. $idle_ex$ is updated to $idle$).

Verification Problems For this case study we consider the following pattern reachability problems (PRP) that represent violation to mutual exclusion and consistency properties. For proving mutual exclusion, we consider a number of PRPs defined by taking as target set of configurations the denotations of a graph with a memory node m and two cache nodes c, c' both linked to m (to model the fact that the cache lines stored in c, c' correspond to that controlled by m) and such that c, c' and the corresponding incident edges have a conflicting state. Formally, we consider graph constraints defined as follows $G = \{1, 2, \{e = (1, 1), e' = (1, 2)\}, \rho_c, \rho_s, \rho_e\}$ where $\rho_s(1) = (\ell, \Lambda_e)$, $\ell \in \{idle, idle_ex\}$, $\rho_c(1) =$

ex , $\rho_e(e) = ex$, and either $(\rho_c(2) = ex$ and $\rho_e(e') = ex)$ or $(\rho_c(2) = sh$ and $\rho_e(e') = sh)$.

We can also formulate other type of consistency properties as PRP. For instance, to check that $idle_{ex}$ corresponds to a memory (line) state in which one cache controller has exclusive access (before or after sending a req_rep message) we can first add the following rule (here bad is a new memory label):

$$((idle_{ex})) \Rightarrow ((bad)) : \forall Q$$

where bad is a new memory label and $Q = \Lambda_e \setminus \{req_rep, ex\}$. The graph $G = \{1, 0, \emptyset, \rho_s, \emptyset, \emptyset\}$ with $\rho_s(1) = (bad, \Lambda_e)$ represents the set of violations to the consistency of the $mode_{ex}$ flag with respect to the current state of the fullmap.

We have implemented a prototype version, SYMGRAPH, of our approximated verification algorithm and tested on the above described properties. SYMGRAPH automatically verifies both properties. The prototype is available at the url

5 Conclusions and Related Work

We have presented a new algorithm for parameterized verification of directory-based consistency protocol based on a graph representation (graph constraints) of infinite collection of configurations. The algorithm computes an overapproximation of the set of backward reachable configurations denoted by an initial set of graph constraints. We apply the new algorithm to different versions of a non-trivial case-study discussed in [20]. We plan to investigate how to extend this approach to deal with parameterized systems in which some of the nodes play both the role of server and client in different instances of a given communication protocol.
